# Simulation of Space Debris Trails

June 9, 2020

## Abstract

### 1 Introduction

The space debris simulation is the aim of the project. The problems of the noises in CCD due to satellite trails and other noises and the collision between satellite are main problem in the astronomy[1]. The space debris are generated due to the collisions between the satellites. These satellite collision create many debris inside the space and become obstacle for other satellites. The collision would become major problem if the space missions continuously grow with time. The collision could be avoided if the trajectory of the satellite is known from some known parameters. In this work, the position of the satellite is obtained by model SGP4[2]. Using this model, the position of the satellite in different coordinate system is found by transformation[3]. The position of the satellite is measured in Alt-Az and Ra-Dec coordinate system. Both system use the reference point to measure the angle between them. Here, the satellite is considered which only moves around the earth and because of that, these coordinate system is used in the model. Other coordinate system like Galactic and Ecliptic are only useful during the planetary motions.

After getting the position of the satellite in appropriate coordinate system, the specifications of CCD are useful to consider for creating realistic picture of the trails. CCD is a device to take the images of the stars or planets. It contains pixels with range of micron in size and works based on the p-n junction in semiconductor[4]. The color or gray value of each pixel is assigned based on the incident photons from the object. After that, the noises, diffraction and some another effects are taken for the imaging of the trails. The noises like sky background, read out, shot, dark noise are considered for the image[5]. Because these noises are related to nature or instruments and can't be avoided. Some of these noise follows Poisson or Normal distribution as described in [5]. After the noise, the diffraction of the object is taken because of the point source. The satellite looks like a point at far distance from the observer. Because of the point source, the image looks little bit blurry. The point source object follows Gaussian distribution intensity profile on the CCD[6]. The point source

is diffracted due to turbulence [7] and the telescope aperture [8]. The effect of the turbulence or aperture depends on the fried parameter [9] and sets two conditions for the diffraction [10]. The diffraction is calculated using standard formulas in the model using fwhm (full width half maximum) as given in [6]-[10].

After the noise and diffraction, the aliasing effect is considered. The aliasing effect is avoided by setting particular frequency which is called Nyquist sampling rate [11]. The aliasing effect [12] is reduced by the point source function in the model and image would be visible clearly without any sharp decrements in the intensity. The point source function, aliasing effect, noise, and diffraction are considered using standard parameters. After that, flux of the object is found by apparent magnitude [13]. The magnitude scale is useful to measure the brightness and the flux of the object. The magnitude of the satellite is measured with reference star like Vega [14]. It is mentioned in the model. The reason behind using the Vega star is because of the zero magnitude value. Using the formulas [14], the flux of the object in the visible band or range is calculated by considering the bandwidth and central wavelength of the band. The flux in the visible range is useful to calculate the total number of photons from the object. These photons fall on the pixels of the CCD and illuminate the pixels. The photons are converted into voltage form by energy transition inside the semiconductor [15]. The electrons are proportional to the quantum efficiency, exposure time, and the area of the telescope aperture. These factors would reduce the total number of the photons incident on the CCD.

Last thing is the atmospheric extinction which is always present in the ground based telescope [16]. The magnitude or flux or brightness of the object is diminished gradually because of the atmosphere of the earth. The atmosphere molecule scatters and absorbs the light incident on them. These scattering and absorption reduce the magnitude value and photon flux. The reduction of the magnitude is calculated for absorption and scattering due to aerosols, ozone layer, and the other gases [17]-[18]. After all these factors, the imaging of the point satellite is obtained within certain field of view of the sky [19]. Using the model, the satellite trails at any time and day could be founded based on these factors. The coordinated system should be understood very well before going in any direction. The next section describes the details of the coordinate system.

## 2 Coordinate system

Space debris are the waste objects or ejected objects from main component of satellite in earth's orbit. Sometimes the remaining objects of collision between satellites. These space debris could damage the other satellites in their trajectory with great momentum. The simulation of space debris is required to stop or predict such type of collisions. Before going towards simulation, coordinate system for earth's satellite objects need to be explained. In astronomy, coordinate system is different from cartesian coordinate system. All the coordi-

nate systems in astronomy and daily used systems are lied into euclidean space. Different coordinate system is used for difference situations. These coordinate systems have different reference axis and points for measurement to avoid the inertial movement of earth's rotation and rotation axis. There are total four types of coordinate system in astronomy [20],

- (1) Horizon
- (2) Equatorial
- (3) Ecliptic
- (4) Galactic

Basic thing for these all coordinate system is celestial sphere. The **celestial sphere** is sphere with center of observer and stars or satellites lie on the sphere. The **great circle** is a circle passing through sphere with greatest radius at any point. The **hour circle** is a great circle passing though poles of celestial sphere [21].

Figure 1: Celestial sphere, hour circle, and great circle

Position of observer is defined by **latitude** and **longitude** on the earth. The fundamental plane is **equator** of earth from where latitude is measured. The **zero point** or reference point from where longitude is measured. Zero point passes through Greenwich, England. Longitude lines are called as meridian and the one passes through zero point is called as prime meridian [21].

Figure 2: Latitude and Longitude

In the Figure 2 Latitude is a point's angular distance above or below the equator. It ranges from  $90^\circ$  north (positive) to  $90^\circ$  south (negative). Longitude is a point's angular position east or west of the prime meridian in units ranging from 0 at the prime meridian to  $0^\circ$  to  $180^\circ$  east (+) or west (-).

## 2.1 Horizon coordinate system

Basic terminologies of this coordinate system are **zenith**, **nadir**, celestial meridian, and horizon. The point above the observer on the celestial sphere is zenith point and below the observer is nadir point opposite to zenith on celestial sphere. Zenith and nadir point are at  $90^\circ$  from horizon with respect to observer. The **celestial meridian** is great circle which intersects the zenith, the nadir, and the celestial poles. Perpendicular to zenith nadir axis is called as astronomical horizon plane [21].

Figure 3: Horizon coordinate system

In the Figure 3, North Point is intersection of the celestial meridian and the horizon that is also closest to the north celestial pole. The south point is the other intersection point. East and West points lie at the intersections of the horizon and the celestial equator. Clockwise, the east point is  $90^\circ$  from the north point.

Figure 4: Altitude and Azimuth in horizon coordinate system

In the Figure 4, the **altitude** ( $a$ ) is angular distance between horizon and star or satellite along the vertical circle passes through satellite or star. Range of altitude is from 0 to 90 degrees. **Azimuth** ( $A$ ) of a body is its angular distance measured eastwards along the horizon from the north point to the intersection of the object's vertical circle (0 to 360 degree). **Zenith distance** is complement of altitude  $90 - a$  [21]. Many telescopes use the altitude-azimuth horizon coordinate because of low cost and high stability. The main disadvantage of this coordinate system is that it varies with time and location on the earth. Therefore, we need universal coordinate system which is constant for every observer on the earth.

Equatorial coordinate system is one option which could consider inertial motion earth like precession, nutation etc.

## 2.2 Equatorial coordinate system

Equatorial coordinate system has two parts, first is 1st equatorial coordinate system (hour angle) and second is 2nd equatorial coordinate system (right ascension). Both coordinate system give same result regardless of observer location and time.

### 2.2.1 1st equatorial coordinate system

The celestial equator is a plane passing through equator of earth and **declination** is angle  $\delta$  measured along the great circle passes through satellite from the equatorial plane. At the equator the declination is zero and it is positive, negative above and below the equator, respectively. The range of declination is from +90 to -90. Another parameter to define satellite along the equator is **hour angle** (HA) which is measured between meridian of satellite and celestial meridian in west direction of celestial sphere.

Figure 5: 1st equatorial coordinate system

The transformation between horizon coordinate system to 1st equatorial coordinate system is matrices multiplication of its component by rotation matrix for each direction x,y, and z. The transformation equation for 1st equatorial to horizon system is given by below equation,

$$I(a, z) = R_3(180) \cdot R_2(90 - \phi) \cdot I(h, \delta) \quad (1)$$

In the equation 1, the a,z,h, and  $\delta$  are azimuth, zenith distance, hour angle, and declination. Here two rotation matrices are applied to equatorial components.  $\phi$  is latitude of observer. The disadvantage of this coordinate system is that

it varies with time of particular location on earth. Therefore, 2nd equatorial coordinate system is most useful to represent the satellite objects [21].

### 2.2.2 2nd equatorial coordinate system

The ecliptic plane is trajectory plane of earth around sun in space. The angle between equator and **ecliptic plane** is 23 degree 26 minutes. Intersection of the ecliptic and celestial equator define the **vernal equinox** and autumnal equinox. Hour circle is a great circle that passes through celestial poles and is perpendicular to the celestial equator. Fundamental reference circle is celestial equator and zero point is vernal equinox. The vernal equinox direction is constant for all observer on the earth. The **right ascension** (RA) of a point it is the angular distance measured eastward along the celestial equator between vernal equinox and the hour circle intersecting the point. It is measured in hours, minutes, and seconds from 0 to 24 hours. The another parameter is declination which is same as in 1st equatorial system.

Figure 6: 2nd equatorial coordinate system

The direction of RA is defined in the Figure 6. To convert from 2nd equatorial to horizon system, **local sidereal time** need to be understood. Our clocks are set to run (approximately) on solar time (sun time). But for astronomical observations, we need to use sidereal time (star time). The Earth rotates 365 times relative to the Sun, but 366 times relative to the stars. So the sidereal day is about 4 minutes shorter than the solar day. Local sidereal time (LST) is hour angle of vernal equinox. Finally,  $HA = LST - RA$  is equation to convert RA to HA. Using equation 1, transformation between HA to azimuth angle is possible [21].

### 2.3 Ecliptic coordinate system

When dealing with the positions and motions of solar system objects, it is often more convenient to refer positions to the mean orbital plane of the solar system using ecliptic coordinates. Fundamental circle is the ecliptic and zero point is vernal equinox. **Ecliptic latitude**,  $\beta$ , is analogous to declination, but measures distance north or south of the ecliptic, attaining  $+90$  at the north ecliptic pole (NEP) and  $-90$  at the south ecliptic pole (SEP).

Figure 7: Ecliptic coordinate system

In the Figure 7, the **Ecliptic longitude**,  $\lambda$ , is analogous to right ascension and is measured from the vernal equinox, in the same direction as right ascension but along the ecliptic rather than the celestial equator. The transformation between 2nd equatorial system to ecliptic is given by,

$$I(\lambda, \beta) = R_1(\epsilon) \cdot I(\alpha, \delta) \quad (2)$$

In the equation 2,  $\lambda$ ,  $\beta$ ,  $\alpha$ , and  $\delta$  are longitude, latitude, right ascension, and declination, respectively.  $\epsilon$  is obliquity of ecliptic plane with equator[21].

### 2.4 Galactic coordinate system

The fundamental circle is galactic equator (the great circle) on the celestial sphere that represents the path of the Milky Way Galaxy. The plane is inclined

at an angle of 62.87 degrees to celestial equator.

Figure 8: Galactic coordinate system

Zero point lies in the direction of the galactic center as seen from Earth. **Galactic latitude** ( $b$ ) of a celestial body is its angular distance north (+) or south (-) of the galactic equator (it ranges from 0 to 90). **Galactic Longitude** ( $l$ ) of a celestial body is its angular distance (from 0 to 360) from the nominal galactic center measured eastwards along the galactic equator to the intersection of the great circle passing through the body [21].

These are all the types of celestial coordinate system. Precession, nutation, proper motion, parallax, refraction are factors cause the deviation of star position. Earth's axial precession is like a spinning top, the direction of the rotation axis executes a slow precession with a period of 26,000 years. **Precession** of vernal equinox occurs due to changing orientation of equatorial plane. As a result, the intersections between the celestial equator and the ecliptic (the equinoxes) move along the ecliptic at a rate of about 50.27 arc seconds per year. To avoid the precession of vernal equinox, we use standard years (like 1950, 2000, 2050) to cite the Equinox. Currently we use Equinox J2000.0. **Nutation** is a small cyclical motion superimposed upon the 26,000- year precession of the Earth's axis of rotation. It is mainly caused by the gravitational attraction of the Sun and Moon, which continuously change location relative to each other and thus cause nutation in Earth's axis. **Proper Motion** is the apparent motion of a star across the celestial sphere at right angles to the observer's line of sight; any radial motion (toward or away from the Sun) is not included. It is observed with respect to a framework of very distant background stars or galaxies. **Parallax** is the angular displacement in the apparent position of a celestial body when observed from two widely separated points. **Atmospheric refraction** causes astronomical objects to appear higher in the sky than they are in reality. This effect even lifts objects from up to 35 arc minutes below horizon to above the

apparent horizon.

### 3 Two line element (TLE)

A two-line element (TLE) set, an example of which is written below, is a data format describing the orbits of Earth-orbiting satellites:

```
1 27843U 03031D 14297.79709235 .00000190 00000-0 10887-3 0 703
2 27843 98.7177 303.6579 0008799 278.1894 134.1004 14.20414232586768
```

A TLE set [22], together with the Standard General Perturbations satellite orbit model 4 (SGP4) model [23]-[24], can be used to determine the position of a satellite at any particular time. TLE elements are used in the propagation of the orbit: epoch, inclination, right ascension of the ascending node (RAAN), eccentricity, argument of perigee, mean anomaly, mean motion, and drag term. The other elements either identify the satellite (satellite number and international designator), check the data integrity (checksum), or provide additional information.

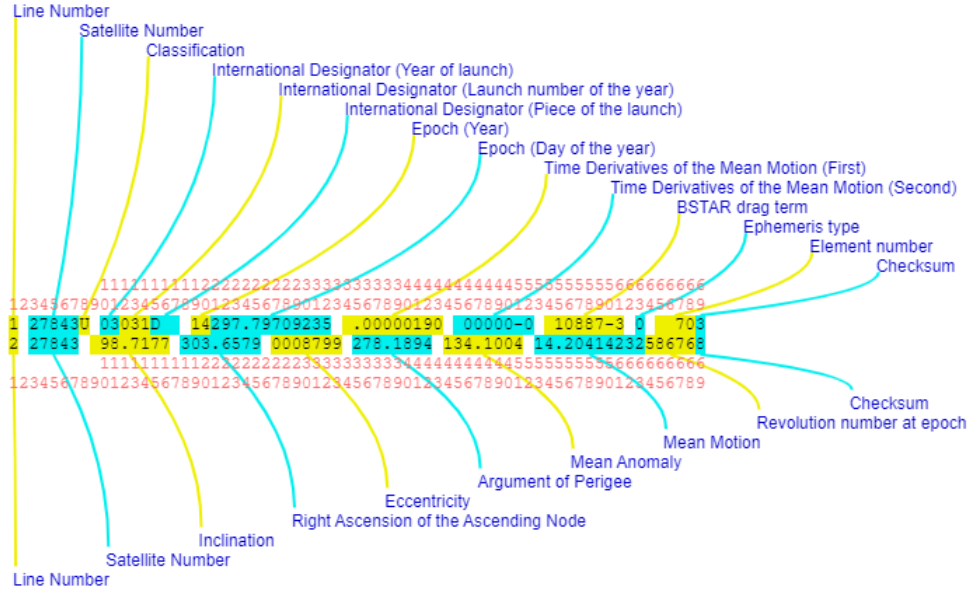

Figure 9: Two line element

In the Figure 9, the first line in the TLE can be thought of as giving properties of the satellite itself, including its identifier, launch properties, and drag terms - which are determined by the cross-section and mass of the satellite [25].

**Line Number** : The line number, as the name suggests, gives the line number within the TLE. (Figure 9)

**Satellite Number** : The satellite number is referred to as the NORAD Catalog Number, NASA catalog number, USSPACECOM object number, or simply Catalog number. The satellite number is a unique sequential 5-digit number assigned by United States Space Command (USSPACECOM) for each earth-orbiting artificial satellite in their Satellite Catalog (SATCAT). The satellite number is assigned based upon when the object was first observed. For a TLE to be valid the satellite number in line 1 must be identical to the satellite number in line 2.

**Classification** : The classification indicates the security classification of the data — all publicly available data will have a 'U' in this field to indicate unclassified data.

**Year of launch** : Year of launch gives the last two digits of the year of launch. As no artificial satellites existed before 1957 (Sputnik 1 was launched into orbit on October 4th, 1957) values in the range from '00' to '56' are assumed to correspond to years in the range 2000 and 2056. Values in the range from '57' to '99' are assumed to correspond to years in the range 1957 to 1999.

**Launch number of the year** : Launch number of the year gives the launch number, starting at 1, of the given year.

**Piece of the launch** : The pieces of the launch are denoted by alphabetic characters, excluding the letters 'I' and 'O'. The 1st piece of a launch is denoted by 'A', and subsequent pieces 'B', 'C', 'D'... 'Z'. The 25th piece would be denoted by 'AA', and subsequent pieces 'AB', 'AC'... 'AZ', 'BA', 'BB', 'BC',... 'ZZ'.

**Epoch year** : Epoch year gives the last two digits of the year of the epoch.

**Epoch day of the year** : Epoch day of the year is the day of the year. A value of 1.0 corresponds to the midnight between December 31st and January 1st. The fractional part of the epoch day gives the time within the day, to an accuracy of approximately 1 millisecond.

**First Time Derivative of the Mean Motion** : This field gives the first time derivative of the mean motion divided by 2. The two time derivatives of the mean motion values give a second-order picture of how the mean motion is changing with time, although it should be noted that these values are not used by the SGP4 orbital model.

**Second Time Derivative of the Mean Motion** : This field gives the second time derivative of the mean motion divided by 6. A leading decimal point is assumed and the last two characters give the applicable power of 10. For example

: 12345-6 is read as  $0.12345 \cdot 10^{-6}$ .

**BSTAR drag term** : The BSTAR drag term is also referred to as the  $B^*$  drag term or the radiation pressure coefficient. Here,  $B^*$  is defined by  $B = \frac{B \cdot \rho_0}{2}$ .  $B$  is ballistic coefficient and  $\rho_0$  is atmospheric density and  $B$  is defined by  $B = \frac{C_D \cdot A}{M}$ .  $C_D$ ,  $A$ ,  $M$  are drag coefficient, cross-section area of satellite, and mass of the satellite.

**Ephemeris type** : The ephemeris type (i.e. orbital model) used to generate the data. 1=SGP, 2=SGP4, 3=SDP4, 4=SGP8, 5=SDP8. These are all the present models for different application. Default value of TLE is 0 which is equivalent to consider the SGP4 model.

**Element Number** : The element set number is a running count of all TLE sets generated by USSPACECOM for this object.

**Checksum** : The checksum is used to help prevent transcription errors in the TLE set. To calculate the checksum, simply add the values of all the numbers on each line (ignoring all letters, spaces, periods, and plus signs) and assigning a value of 1 to all minus signs.

**Line 2** : The second line in the TLE can be thought of as giving the properties of the orbit of the satellite.

**Line number** : The line number, as the name suggests, gives the line number within the TLE.

**Satellite number** : The satellite number is also referred to as the NORAD Catalog Number.

**Inclination  $i_0$**  : The angle, in degrees, between the equatorial and the orbital plane. The value lies between 0 and 180.

**Right Ascension of the Ascending Node  $\Omega_0$**  : The angle between the vernal equinox and the point where the orbit crosses the equatorial plane (travelling north). The value lies between 0 and 360.

**Eccentricity  $e$**  : The eccentricity of the orbit. A leading decimal point is assumed, such that if the value appears as 0008799 is understood to mean 0.0008799.

**Argument of perigee  $\omega_0$**  : The angle between the ascending node and the orbit's point of closest approach to the earth (perigee). The value lies between

0 and 360.

**Mean anomaly  $M_0$**  : The angle, measured from perigee, of the satellite location in the orbit referenced to a circular orbit with radius equal to the semi-major axis. The value lies between 0 and 360.

**Mean motion  $n_0$**  : The value is the mean number of orbits per day the object completes.

**Revolution number at epoch** : The period from launch to the first ascending node is considered to be revolution 0 and revolution 1 begins when the first ascending node is reached.

**Checksum** : It is same as line 1's checksum.

The format of TLE is given by,

```
1 NNNNNC NNNNNAAA NNNNN.NNNNNNNNN +.NNNNNNNNN
      +NNNNN-N +NNNNN-N N NNNNN
2 NNNNN NNN.NNNN NNN.NNNN NNNNNNNN NNN.NNNN NNN.NNNN
      NN.NNNNNNNNNNNNNNNNN
```

N is any digit 0-9 or, in some cases, a space. A is any character A-Z or a space. C is a character representing the classification of the element set, which is always U for publicly released data. + is a space, a minus sign, or a plus sign (which is equivalent to a space). All the description of the TLE is taken from [25]. After getting information of satellite's parameters which define the trajectory, the model sgp4 is used for position determination.

## 4 SGP4 model and simulation

The SGP4 stands for simplified perturbations model [24]. During the flight of satellite or space debris, its trajectory continuously changes its parameters inclination, right ascension, time period etc because of external perturbations from sun, moon, earth's precession, and nutation. The model contains very complicated factors. The python has a package called as SGP4 which consider all these factors for low orbiting satellites like space debris. The model takes the input of TLE and time in UTC. It will give respond in xyz coordinate in the ECI frame. ECI(Earth centered inertial frame) consider the center of earth as origin. The x axis is the line passing through vernal equinox . The y axis is the perpendicular to x in the direction of z cross x. The z axis is rotation axis of earth. Using ECI frame, right ascension and declination could be found very easily. Right ascension is the angle between satellite and vernal equinox or x axis [24]. The declination is the angle between vector of satellite and plane xy. The python editor is used to find RA(right ascension) and Dec(Declination).

After all manipulation the transformation is done between RA, Dec to altitude(Alt) and azimuth(az) angle. The transformation needs latitude and longitude of location. Because Alt-Az system depends on location of observer while RA-Dec is independent on observer's location. The transformation also include the Julian day from year 2000.

The verification of the model has been done by several ways.

#### 4.1 Model and Result

In this subsection, the results of satellite's coordinates are obtained through the simulation of SGP4 model using Python. The SGP4 model as mentioned is very complicated and includes so many perturbations like solar radiation, moon and earth's gravity, etc. The main input of the SGP4 model is TLE of the satellite. The implementation of SGP4 model in Python is done by Brandon Rhodes [26]. As input of TLE lines, the output is given in Cartesian coordinates and in terms of position and velocity components at given particular time. The frame of reference that is used in output is ECI (Earth centered inertial). ECI has origin at Earth's center. Its x axes is same as direction of vernal equinox direction. In the model, (1,0,0) is taken as vernal equinox direction with origin as Earth's center. The z axes of frame is the rotation axes of Earth, and y axes is cross product of z and x [27]. After deciding all the axes, the coordinates of position and velocity which are called as Phase points are converted into Right ascension and Declination.

RA and Dec are independent of the observer position and the results are given below; The TLE data of ISS zarya [22] on 11-4-2020 and time 5:19:50 is given by,

```
1 25544U 98067A 20102.22211638 .00001877 00000-0 42676-4 0 9992
2 25544 51.6441 319.8604 0003740 104.4166 46.6925 15.48685017221631
```

The TLE is changed continuously with time and the updating of TLE is done regularly by NORAD TLE database [22]. If we want to find the position of ISS zarya satellite on 13-4-2020 and time 5:20:30, the model takes the input of these parameters and output will be in Phase points in ECI. The Phase point at that particular time and data are as follows, In the table 1, the results are in km

Table 1: Phase points in ECI frame for ISS zarya

Components	Position	Velocity
x	-2307.602	-5.546
y	5869.336	0.107
z	2527.379	-5.288

unit. From the results, the x and z component of velocity are -5.546 and -5.288 km per sec. Using the geometry of the reference frame, the angular direction between satellite position vector and vernal equinox vector will be our RA and angular direction between position vector and equatorial plane or xy plane will

give the Declination.

After applying the same concept, the results are given as follows, **RA = 7.431 hours and Dec = 21.838 degrees**. That means vernal equinox direction is 7.431 hours behind the satellite. Suppose we want to measure the elevation or altitude and azimuth angle of the satellite which depends on the observer location, we need to define the latitude and longitude of the observer to find the coordinates. Suppose the current position of the observer is **23.014 latitude and 72.775 longitude**. The elevation is the angle between horizon plane made by observer and satellite vector position, and the azimuth is the angle between satellite direction and north direction with respect to the observer. The results are as follows, **Elevation or Altitude = -50.47 and Azimuth = 58.572**. From the geometry, the multiple parameters are obtained like distance between satellite and observer, velocity, etc. The simulation of satellite trajectory is also done by matplotlib library. Using that the plot between altitude and azimuth angle was obtained and the result is as follows,

Figure 10: 3D plot of altitude and azimuth angle

The 3D result of altitude and azimuth angle variation of satellite with time (Julian time) is given in the above figure. The time interval between starting and

end point of satellite is taken as 2 hours. That means the trajectory that is given the figure has starting time 6:0:0 to 7:59:59 on same date. The variation of azimuth angle is from 0 to 360 degree while the elevation varies from 0 to around -70 degrees. That trajectory is given in space time geometry. In the two dimensions, the phase plot is given as follows,

Figure 11: 2D plot of altitude and azimuth angle

The 2D plot is same as 3D but the time dimension has been omitted. It is apparent that the satellite completes the one cycle of its motion around the earth and go forward little bit. The starting point of the satellite and end point are not matching very well that is because of the perturbations that affect the satellite trajectory.

Similarly, the plots for coordinate which is independent of the observer are also obtained in Ra-Dec. The 3D profile of satellite trajectory in RA-Dec coordinate system is given below,

Figure 12: 3D plot of right ascension and declination angle

The trajectory looks same as altitude and azimuth profile. The two dimensional contour is given below,

Figure 13: 2D plot of right ascension and declination angle

Here, the shape looks like infinity shape. Also, the maximum declination of any satellite trajectory will be equal to inclination of its orbit. Here from the approximation, the maximum declination is around 51.3 degree which is inclination of the orbit. This is low earth orbit satellite which has mean motion around 15 to 10 times. The geostationary satellite has mean motion around 1 that is why it took 24 hours to complete the whole orbit. We made the trajectory of a geostationary satellite and it came out with very interesting results which are shown below.

The Japanese satellite **Quais-Zenith Michibiki-1** has been taken as geostationary satellite which has orbital period time is same as earth's rotation period [22]. The TLE of the given satellite is,

```
1 37158U 10045A 20115.95841260 -.00000085 00000-0 00000+0 0 9991

Here, the epoch time, when the location of the satellite position was measured, is 24-4-2020 at 23:00:07. The result of the data we got on 26-4-2020 at 1:30:30. On the particular mentioned date and time, the results are as follows,

In the results are in km and it is in the frame of ECI reference. The actual orbital trajectory of the QZS-1 looks like the infinite shaped [28]. The results of

Table 2: Phase points in ECI frame for Qausi-Zenith -1

Components	Position	Velocity
x	35189.470	-1.001
y	602.082	2.732
z	-18603.977	-1.450

the model on 26-4-2020 at 1:30:30 are shown below and it has better agreement with the trajectory.

Figure 14: 3D plot of right ascension and declination angle for QZS-1

The QZS-1 moves from -41 to 41 degree with respect to the equator. The above figure is shown in three dimensions and it completes the orbit twice in 48 hours. The 2D projection is given below,

Figure 15: 2D plot of right ascension and declination angle for QZS-1

The shape looks like infinite and also this same result occurs in alt-az profile which is shown below,

Figure 16: 2D plot of altitude and azimuth angle for QZS-1

The 3D plot is as follows,

Figure 17: 3D plot of altitude and azimuth angle for QZS-1

This is for geosynchronous or geostationary satellite with time period of 24 hours to complete a orbit at location of latitude 23.0143, and longitude 113.7751.

The Microsat-R satellite from India was launched on 24-1-2019 and it was an earth observing satellite manufactured by DRDO and launched by Indian Space Research Organisation and was meant for military use. It was served as target test for the destroying the satellite. India did Mission Shakti which destroyed the Microsat-R at altitude of 280 km. It was just test but mission produced around 400 pieces [42]. Also, around 20 to 24 debris are having apogee higher than ISS orbit. Here it is the TLE of a Microsat-R debris,

#### MICROSAT-R DEB

```
1 44134U 19006V 20118.95480144 .00081665 21016-5 97063-3 0 9998

```

The epoch time, when the TLE was obtained, is on 27-4-2020 at 22:54:55 and the results of the coordinates of position and velocity which are given below on 29-4-2020 at 5:30:30 using the model.

The nature of the trajectory of satellite is given in the below figure,

Table 3: Phase points in ECI frame for Microsat-R

Components	Position	Velocity
x	2361.119	1.682
y	-4153.069	-5.312
z	-5593.125	4.518

Figure 18: 2D plot of altitude and azimuth angle for Microsat-R

Figure 19: 3D plot of altitude and azimuth angle for Microsat-R

The shape of the profile is very unusual because of it is a part of satellite which was exploded. This will make the shape of the orbit very random with high eccentricity. The three dimension and two dimension of the right ascension and declination are given below,

Figure 20: 2D plot of right ascension and declination angle for Microsat-R

Figure 21: 2D plot of right ascension and declination angle for Microsat-R

After knowing the position of the satellite with help of the SGP4 model, the trails simulation is obtained using these positions of the satellite within field of view. Now, the next part is the image processing mechanism in CCD and satellite trails simulation.

## 5 Charge coupled device (CCD)

Charge Coupled Devices (CCDs) were invented in the 1970s and originally found application as memory devices. Their light sensitive properties were quickly exploited for imaging applications and they produced a major revolution in Astronomy. CCD is highly sensitive device for detecting photons from celestial objects. It is made up of large number of light sensitive small areas which are called as pixels. The photon emits the electron from one pixel, and electron works as data of that particular photon. Basic principle behind CCD is photoelectric effect. Electron will be released when photon energy exceeds the work function of material. Based on the number of electrons in each pixels, intensity profile will be obtained [30]. The liberation energy of electron from material is given by  $E = h \cdot \nu$ .

Figure 22: Generation of electron

Figure 22 describes the generation of electrons from a pixel. Photons incident on plate and generate the electrons. Pixel is made up of metal oxide, p-type and n-type semiconductor materials. Two gates are used for transportation of charges from one pixel to another for data analysis [15] as shown in below figure.

Figure 23: Transfer of charge in CCD

Potential well is a place where electrons will be stored using positive bias at metal electrode. As more and more light falls onto the CCD, then the potential well surrounding this electrode will attract more and more electrons until the potential well is full (the amount of electrons that can be stored under a pixel is known as the full well capacity). To avoid the full capacity, CCD needs shutter to prevent photons. That's why the exposure time is necessary thing for the imaging. CCD has rows and columns on its top plate and size is defined by number of rows and columns. The resolution of the CCD is defined by the size of the pixels, also by their separation. In most astronomical CCDs the pixels are touching each other and so the CCD resolution will be defined by the pixel size, typically 10-20  $\mu m$  [15].

Figure 24: Pixels arrangement in CCD

In the figure 24, the charges are transferred vertically downwards, then hor-

horizontally transportation is done using gate voltage. This type of process is described in below figure.

Figure 25: Pixel readout process

The output of each pixel is in analog mode which needs to be converted into digital form. After processing of data, intensity profile is created. This profile is useful to get color image of an object using RGB (red green blue) filters and gray scale. Combination of these filter gives the final colored image of celestial objects. There are other factors like efficiency of charge transfer and noise. All these contribute in the low resolution of image. There are some mathematical techniques to reduce these kind of inaccurate data involvement [15].

## 5.1 Noises and efficiency of CCD

Noise sources are divided into two parts temporal and spatial. Temporal noise can be reduced by frame averaging, while spatial noise cannot. However, some spatial noise can be removed by frame subtraction or gain/offset correction techniques [5]-[31].

### 5.1.1 Shot noise

Shot noise is photons coming from randomly all over space which is nature's fundamental limit which can't be avoided. This noise is related with source of the object. The number of photons coming from the source vary with time and follow the Poisson distribution. Since the time between photon arrivals is governed by **Poisson statistics**, the uncertainty in the number of photons collected during a given period of time is simply  $\sigma_{shot} = \sqrt{S}$ . Here S is signal expressed in electrons. So a 10,000-electron exposure will have a shot noise of 100 electrons [5]-[31].

The noise associated with the source and this could not be removed very easily.

Because this noise follows the Poisson distribution. Even the source has photon flux around 100, it would have noise approximately 10 photon. That means temperature of CCD, exposure time, area of telescope could not remove this particular noise.

### 5.1.2 Reset noise

By sensing the capacitor, we can find the voltage domain of collected charged packets from each pixels. Before measuring each pixel's charge packet, the CCD's sense capacitor is reset to some reference level. There is an uncertainty in this voltage related to thermal noise generated by the channel resistance. It is given by  $\sigma_{reset} = \sqrt{4kTB\Delta f}$ . Where  $k$  is boltzmann constant,  $T$  is temperature,  $B$  is the noise power bandwidth (Hz),  $R$  is the resistance. It is also expressed in  $\sigma_{reset} = \frac{\sqrt{kTC}}{q}$ . Here  $C$  is capacitance of sense and  $q$  is fundamental charge. Most manufacturers of CCD cameras include circuitry that completely eliminates it.  $R$  is the effective resistance and it is around 350 ohm. With bandwidth of 1 MHz and temperature at  $T = 193$  K the reset noise in V/rHz is  $1.9314 \cdot 10^{-6}$ . Therefore, the rms value is obtained by dividing the value through sensitivity. The sensitivity is  $10^{-6}$  and the final reset noise in rms electron will be around 2 per pixel [5]-[31].

### 5.1.3 White noise

This is readout noise at output of amplifier. The output amplifier has a resistance and noise is associated with this resistance and the temperature. The effective resistance in this case is the output impedance of the source,  $R_{out}$ . This type of thermal noise is sometimes called 'Johnson noise'. It is represented by  $\sigma_{white} = \sqrt{4kTB R_{out} \Delta f}$ . The unit of this noise is V/rHz and it is converted to rms electrons by dividing sensitivity. The value of  $k$  is taken in J/K unit and bandwidth is taken normally as 1000000 Hz from the standard CCD iKon-M 934 Series. The  $R$  is resistance of output channel of the CCD. It is taken as  $2000 \Omega$ .  $T$  is 193 K and after all these values the  $\sigma_{white}$  is  $4.617 \cdot 10^{-6}$  V/rHz. Considering the sensitivity  $10^{-6}$ , the rms electrons of this noise is 4.617 rms electrons per pixel [5]-[31].

### 5.1.4 Flicker noise

This noise is dependent on the inverse of frequency  $f$ . Higher the frequency, lower the noise in the image. The noise power is given by  $\frac{V^2}{Hz}$  and it is decreased by 10 factor with each decade increase in frequency. It is caused by surface and bulk traps due to defects and contaminants that randomly capture and release carriers. Many natural systems exhibit  $1/f$  behavior. They have in common a collection of states that turn on and off individually with randomly distributed time constants. Generally, the approximate value of the flicker noise is around  $100 \cdot 10^{-9}$  V/rHz. The unit is V/rHz and to convert into electrons, the sensitivity of the CCD plays a role. Dividing sensitivity to V/rHz (flicker

noise), the unit conversion would be in rms electrons per pixel. That's why the flicker noise follows the Gaussian or Normal distribution. After taking sensitivity as  $10^{-6}$ , the final answer in rms electrons would be 0.10 per pixel [5]-[31].

### 5.1.5 Clocking noise

Number of clocking circuits are required to accumulate and process the signal from input to output. The noise is associated with output waveform called as clocking noise due to the circuits. It is dependent on square root of clocking frequency. The clocking noise is not considered because of it is very less compared to other noise.

These reset noise, white noise, flicker noise, and clocking noise come into read out noise. Because these noises are produced during the reading of the image. It is because of the resistance and frequency of reading and in this process, some of the electrons are escape from the channel. The read out noise is sum of the these noises. Therefore read out noise is equal to white noise + reset noise + clocking noise + flicker noise. The reason behind the in-dependency of these noise from the exposure time is because these noises are generated during the reading of the image as name suggests. Therefore, after some time or after exposure time when image is ready to read, processor takes each pixels voltage and converts into digital form with certain frequency. And during this process, the read out noise will be generated.

As mentioned before, these noises are dependent on the bandwidth of the frequency, resistance in the channels and temperature. After dividing the noise by sensitivity, the final output would be in rms e-. These noises follow the normal distribution and the output of rms value would become standard deviation of the normal distribution with mean value of zero [5]-[31].

Table 4: Read out noise's variation with temperature in 1024 x 1024 pixels CCD (1 MHz)

Temperature (K)	Read out noise (rms per pixel)
193	7.0255
233	7.7094
273	8.3368
303	8.7775

This variations in table 4 are at 1 MHz frequency bandwidth in the CCD. The rate of the variation with temperature is decreasing with temperature. Because the read noise mostly depends on square root of temperature.

In the table 5, the noise become very large at 100 MHz frequency bandwidth. This noise still around 70 rms e- per pixel at  $T = 193$  K. In imaging process, temperature doesn't change very much but bandwidth does. The read out noise is verified [32] with at temperature 193 K.

Table 5: Read out noise's variation with temperature in 1024 x 1024 pixels CCD (100 MHz)

Temperature (K)	Read out noise (rms per pixel)
193	69.3558
233	76.1949
273	82.4681
303	86.8759

### 5.1.6 Dark current

Dark current is the result of imperfections or impurities in the depleted bulk silicon or at the silicon-silicon dioxide interface. These sites introduce electronic states in the forbidden gap which act as steps between the valence and conduction bands, providing a path for valence electrons to sneak into the conduction band, adding to the signal measured in the pixel. Because of the imperfections, the small thermal agitation could jump the electron easily. The dark current is generated because of thermal fluctuations. Therefore, CCD is placed in very cooled place to avoid this noise addition. There are other two noise related with surface and bulk [5]-[31]. These noises are generated because of carelessness in the manufacturing of it surface.

Therefore, the dark current is given by,

$$Dn = 2.5 \cdot 10^{15} \cdot A \cdot I \cdot T^{1.5} \cdot e^{-\frac{E}{2kT}} \quad (3)$$

The unit of the  $Dn$  is electrons/pixel/second. The  $T$  is variable temperature surrounding the CCD.  $A$  is the area of a pixel in  $cm^2$  and  $I$  is a dark current at temperature 300 K. It changes with quality of the CCD's. In general, the value of  $I$  lies between 0 to 2 nanoamperes/cm/cm. But in the model, the value is taken as 0.018. Also  $k$  is the boltzmann constant in eV/K. Finally, the  $E$  is the band gap energy in silicon diode which also varies with temperature. These reference values are taken from standard CCD iKon-M 934 [32].  $E$  is defined by,

$$E = 1.1557 - \frac{7.021 \cdot 10^{-4} \cdot T^2}{1108 + T}$$

The  $E$  is in the eV unit. After considering all the values of these variables and constants for standard CCD like iKon-M 934 Series. The values are given as follows,  $T = 193$  K,  $I = 0.018$  nanoamperes/cm/cm,  $A = 169$  square micron,  $k = 8.6173 \cdot 10^{-5}$  eV/K. After putting all these numbers into equation 3, the  $Dn$  is 0.0003038 e-/pixel/second [32].

To find the total dark noise using dark current, the multiplication operation of time and number of pixels are done with  $Dn$ . The time represents as exposure time. Thus, the more the exposure time, the more the dark noise which varies with linearly. Also, the variation of the dark noise with temperature is very obvious from the intuition. It is fact that the temperature rise would increase the dark noise. The dark noise increases with exposure time. In the below figures, the time is taken as variable in  $s$  between 0 to 1000.

Figure 26: Dark noise at  $T = 193$  K

From the figure 26, the dark noise increases with time in linear fashion. Because noise is proportional to the time directly. The unit of the noise is e- per pixel. From the figure, the output electron at temperature  $T = 193$  K, the noise is negligible and the maximum noise at  $t = 1000$  s is around 0.27 e- per pixel.

Figure 27: Dark noise at  $T = 233$  K

Here also, the variation is proportional to time at temperature  $T = 233$  K and the maximum value is 160 e- per pixel which is not negligible. It could affect the quality of the image.

Figure 28: Dark noise at  $T = 273$  K

In the above figure, the maximum value is 14000 which is very large noise and could dominate the point image. Therefore, temperature  $T = 273$  K is not desirable and feasible. To avoid this noise, the CCD is kept at very low temperature around 190 to 230 K. The cooling process slows down the thermal fluctuations inside the sensor. All the results are verified with [32].

## 5.2 sky background noise

The noises from other stars or any interference like light, bulb could affect the image quality. Still, the image can't get rid of the sky noise from different stars and celestial bodies. It is random and follows the Poisson distribution. The sky background is given in unit of  $\text{mag/arcsec}^2$ . Till now, the brightness or intensity of an object was given by magnitude. But that object was a point source. This kind of point sources have only magnitude because a telescope cannot resolve the surface of the distant stars. It is similarly for satellite. Satellite's brightness is given in magnitude. But for the extended source which has apparent surface, its brightness is given in  $\text{mag/arcsec}^2$ . Thus, the field of view will decide how many photons will fall on the CCD randomly. Another parameter, time exposure, will also be essential to consider. If the field of view and exposure time are high, then noise contribution from the sky would be very high. Generally, the sky brightness has a value of around 21  $\text{mag/arcsec}^2$  in visible range [33]. Therefore,

around 600 ADU will be assigned to each pixel if the exposure time is 1s and field of view is in 180 X 180 arc second. The formula of the sky background noise is given by [33],

$$n_{sky} = f_v^2 \cdot \pi \cdot 10^{-0.4 \cdot m_v} \cdot 8.8 \cdot 10^9 \cdot QE \cdot t \cdot D^2 \cdot \pi \quad (4)$$

In the above equation 4, the  $QE$  is quantum efficiency of the CCD and  $D$  is the diameter of the telescope aperture.  $f_v^2$  is the field of view of the CCD and  $m_v$  is the magnitude of the sky. The field of view has arc-sec unit and diameter of the aperture in meters. The  $n_{sky}$  is total sky noise within the field of view. Therefore, to calculate the noise per pixel, the output is divided by total number of pixels to get average number. Also, this noise follows Poisson distribution. Suppose, the field of view  $f_v = 180$  arc-sec with sky background apparent magnitude  $m_v = 21$  magnitude/arc-sec<sup>2</sup>. Also, the  $D = 1.2$  m,  $QE = 60$  %, and exposure time  $t = 1$  s are taken as standard values. The sky background incoming photon numbers would be 966942659.85. This value is spread over the all pixels and illuminates them. To calculate the average value of photons per pixel, the value is divided by total number pixels. For example, in 1024 x 1024 CCD, the average number is 922 photons. The associated ADU is 600 in gray scale [33].

Figure 29: Images with sky background noise and without noise

There are many techniques to remove the noise. For example, to remove the sky background noise, one blank frame of image is taken to measure the noise with particular time and field of view. After subtracting this frame from the real image, it would eradicate the noise.

The signal to noise ratio is the last thing that should be taken care because the more the signal to noise (SNR), the more the signal would be strong. The SNR is dependent on read out noise, dark noise, sky noise, shot noise. After

the calculations, the dependency of SNR is given below [5]-[34],

$$SNR = \frac{S_0 \cdot Qt}{\sqrt{S_0 \cdot Qt + S_s \cdot Qt n_p + S_d \cdot t n_p + R^2 n_p}} \quad (5)$$

In the equation,  $S_0, S_s, S_d, R$  are noise related to shot, sky, dark and read out, respectively.  $Q, t, n_p$  are quantum efficiency, exposure time, and number pixels spread by object or point source.

Figure 30: Signal to noise ratio for 2500 electrons per pixel per second

The SNR increases with exposure time but in linear fashion. It varies with quadratic nature and for infinite exposure time the SNR would be saturated at one point [34]. But the exposure time increases the strength of the signal as it is visible from figure 30

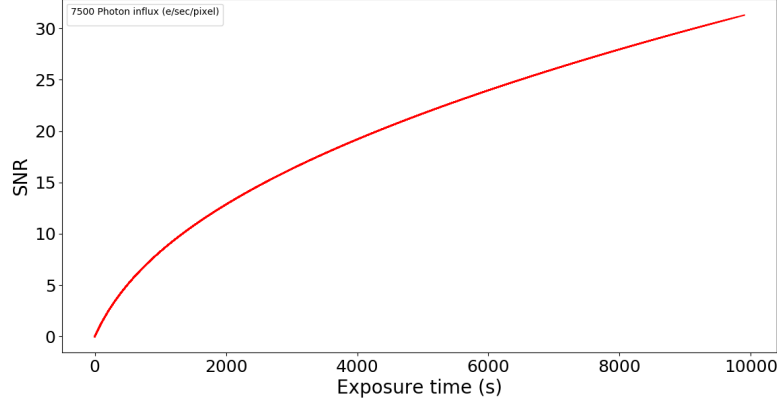

Figure 31: Signal to noise ratio for 7500 electrons per pixel per second

Also, the difference between figure 31 and 30 is that photon flux on a pixel. Figure ?? has 2500 photons flux while figure 31 has 7500 photons flux. But for 7500 photon flux, the SNR is lower than 2500 photon flux. The higher the photon flux, the less the SNR and signal would be weak. SNR is essential to calculate and analyze the image quality [5] and [34]. Next section describes the magnitude and satellite trails details.

## 6 Observation of satellite trails and its magnitude

TLE data is come from the observation of space debris using ground telescope. It uses high quality CCD for the measurement. Its magnitude plays role to find distance and its variation with time and position. From that, velocity could be found and its related parameters. It is also useful to remove space debris trails from pictures for analysing. The brightness or apparent magnitude of satellites come from sunlight. Sunlight incident on the satellite's material like solar plates or ceramics etc. After reflection of incident light, it will come to observer on the earth. But before that, light passes through atmosphere of the earth and loses its brightness due to scattering and absorption. The next section describes the attenuation of apparent magnitude of satellite using various equations. The brightness of satellite depends on different parameters like albedo (reflectivity), area, distance, phase angle, and magnitude of sun [14].

The absolute magnitude of any celestial object is the apparent magnitude of that object when it is far from observer at 10 parsec distance. 1 parsec is equivalent to  $3.1 \cdot 10^{13}$  km. Apparent magnitude is the magnitude value of object when it is observed from earth. In the parameters, albedo is ratio between reflected

light and incident light. It varies with wavelength. Moon has 0.12 albedo value in visual range of wavelength [35] and [36]. ISS (zarya) has 0.6 to 0.7 because of solar plates . Area is the cross-section area of object when observed from earth. Generally for satellites, it is assumed to be spherical shape with certain radius. Phase angle is the angle between sun to satellite direction and satellite to observer direction. It is shown in below figure,

Figure 32: Phase angle of satellite

When phase angle is zero, moon will be at full moon phase. Magnitude changes with phase angle. At the 90 phase angle, moon would be at first quarter phase. Magnitude is kind of scale to describe the brightness. Brightness and magnitude has logarithmic relation, therefore high brightness star would have negative or minimum value of magnitude. As the magnitude increases, the brightness will be decreased [37].

Figure 33: Magnitude scale

As mentioned above, the scale appears to work 'in reverse', with objects with a negative magnitude being brighter than those with a positive magnitude. The more negative the value, the brighter the object. The absolute magnitude is measured with reference to brightest star Vega. Apparent magnitude is assumed to be zero for Vega star for the reference. With reference to that, Sun has -26.74 apparent magnitude and 4.83 absolute magnitude. Moon has apparent magnitude of -12.6 [37]. ISS satellite has maximum -6 apparent magnitude.

$$m_2 - m_1 = -2.5 \cdot \log_{10} \left[ \frac{b_2}{b_1} \right] \quad (6)$$

In the equation , the  $m_2, m_1$  are apparent magnitude of star 2 and 1, respectively. Similarly,  $b_2, b_1$  are apparent brightness of them [37]. When comparing apparent and absolute magnitude of a star, we get the distance modulus and it is given by,

$$m - M = 5 \cdot \log_{10} [d - 5] \quad (7)$$

Here  $m, M$  are apparent and absolute magnitude of a star and  $d$  is the distance between star and observer. Brightness and luminosity is related by  $B = \frac{L}{4\pi d^2}$  [38].

The apparent magnitude of satellite is defined by various equations. The reflection of the light could be specular or diffusive. Based on that there are various formulas. The general formula is given by [14],

$$m = -26.58 - 2.5 \cdot \log \left[ \frac{A\gamma F(\phi)}{R^2} \right] \quad (8)$$

$A$  is the cross-section area of satellite when it is observed from earth.  $\gamma$  is albedo or reflectivity of satellite's material.  $R$  is the distance between satellite and observer.  $F(\phi)$  is the function of phase angle which is defined by [14],

$$\cos(\theta) = \frac{|r_{sat} - r_{obs}|^2 + |r_{sun} - r_{sat}|^2 - |r_{sun} - r_{obs}|^2}{2 \cdot (|r_{sat} - r_{obs}|)(|r_{sun} - r_{sat}|)} \quad (9)$$

$\theta$  is phase angle and  $r_{sat}, r_{sun}, r_{obs}$  are position of satellite, sun, and observer, respectively in same coordinate system. In the equation 8, -26.58 is apparent magnitude of sun.  $F(\phi)$  varies with shape of satellite and its surface. For example, satellite is a sphere with diffusive reflection then  $F(\phi)$  is given by  $F(\phi) = \frac{2}{3\pi^2} \cdot [(\pi - \phi)\cos(\phi) + \sin(\phi)]$ , where  $\phi$  is in radian. If satellite has specular reflection surface then  $F(\phi) = \frac{1}{4\pi}$  [39]. Here apparent magnitude of satellite  $m$  is without earth's atmosphere. We need to take consideration of atmospheric extinction which scatter or absorb the light during its path. Atmospheric extinction is given in next section.

Here the phase angle is very important even in the moon's phases, it is due to phase angle. The earth blocks little bit portion of the moon to illuminate it. And we see the phases of moon. Similarly, satellite's magnitude changes with phases. The phase angle  $\theta$  is defined in the equation 9 [39]. From the equation it is apparent that the phase angle is dependent of the distances between earth and sun. Also, the magnitude of the satellite depends on albedo, surface area and distance between observer and satellite. Albedo depends on the surface properties. Basically, satellite is powered by solar plates and this plates have good reflective because of the glass. The surface area also plays the role in the magnitude. The higher the area, the more the apparent magnitude. And last one is distance. If the distance is very large then the intensity would attenuation with distance. This will decrease the magnitude.

But the phase angle is very crucial to observe the satellite. Because with time, the phase angle changes and the apparent magnitude. Sometime, satellite totally become invisible if the phase angle is not beyond certain value.

Before calculating the phase angle, sun's position is very important to calculate the distances. For the moon, 0 degree is the position when the moon is in opposite side of the earth during the night. Because of that we don't see the moon. That phase is new moon phase. Moon takes around 28 days to rotate around the earth. Therefore, the phase angle changes with time-period of 28

days. After certain days, moon comes in such phase that, it appears only half of it. This position has phase angle 90 degree. And at 180 phase, the phase is full moon when moon appears to be full. Because the sun-light totally incidents on the whole surface of the moon and illuminates it [41]. The albedo of the moon is around 0.2. The phases of the moon is given below,

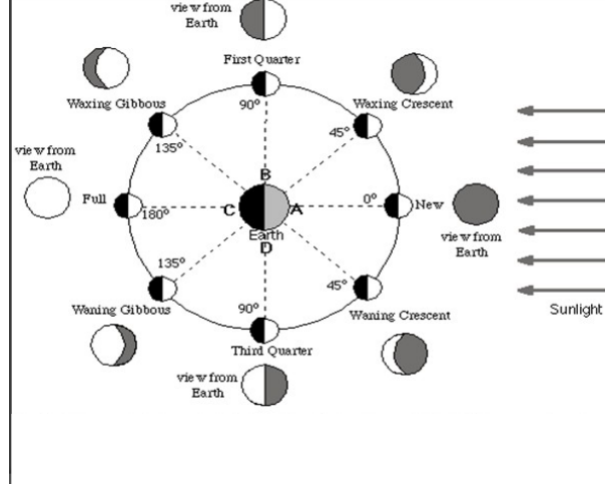

Figure 34: Moon's phases

In the above section, the three satellites have been taken for finding the position. Here, the phase angle of these satellites have been given below with some assumptions of its size and albedo.

## 6.1 Results of phase angle

(1) **ISS (Zarya)** As mentioned about the ISS satellite's TLE and its position with time, it has size around 12.5 m X 4.1 m in length and diameter [?]. Therefore the average size of the satellite is taken as 10 meters to calculate the surface area of the circular disk if we assume the satellite a sphere. The albedo of the satellite is around 0.75 and distance is variable which changes with time. Mostly, the orbit of this satellite is almost circular with less eccentricity. Thus, distance would be around 420 km [?]. After incorporating all these values, the apparent magnitude and phase angle is found as shown in below figures.

Figure 35: The variation of phase angle with elevation of ISS satellite

In the above figure, the phase angle is started from the 55 degree to 170 degree. The maximum value of the elevation is 22.5 degree on 30-4-2020 at location of 23 latitude and 72.7 longitude. Also, the maximum apparent magnitude is around 6 and minimum at -2.5. From the observation, at 170 phase angle which is maximum has apparent magnitude -2.5. It is also verified that ISS satellite has minimum -3 apparent magnitude from the shortest distance at 180 phase angle. The satellite starts dimming as the elevation of the satellite increases. This increment changes the phase angle and the magnitude. At last, when phase angle becomes around 55, the magnitude becomes around 5 to 6 which is very hard to notice with naked eye.

Figure 36: The variation of apparent magnitude with elevation of ISS satellite

Another result of the Microsat - R is shown in the below figure. The size of the debris is taken around 5 to 10 cm with 0.3 albedo value [42]. The trend looks very randomly and the debris passed through location at 49.0143,72.7751 around 4 to 5 times a day. The maximum angle of the elevation is 70 degrees with phase angle at 80. The curve with maximum elevation has minimum phase angle at 70 and ends at 100. Again, the sun plays the main role for the illumination of any objects.

Figure 37: The variation of phase angle with elevation of Microsat - R

After observing the phase angle of the debris, the apparent magnitude is main factor to analyze that it is visible to naked eye. If the apparent magnitude is greater than 6 to 7 then is not visible with our eyes.

Figure 38: The variation of apparent magnitude with elevation of Microsat - R

It is assumed that the debris has size of 50 cm with 0.5 albedo value. Sometimes, it could have 0.2 albedo with size of 10 to 5 cm. Debris are very small that it is hard to discernible due to turbulence and atmospheric extinction of the atmosphere [42]. From the figure 38, the maximum apparent magnitude is at 12 at elevation of 12 degree. The minimum apparent magnitude is 3 to 4 at elevation of 4 to 5 degree. The trends follow the same behavior as phase angle. Here, the average distance is around 418 to 430 km. This magnitude is attenuated by atmosphere by scattering and absorption which is give in the next section.

## 7 Atmospheric extinction

As light makes its way through the Earth's atmosphere, some photons collide with atoms, molecules, water droplets, grains of dust, and other objects. These photons may be absorbed by the objects or they may be scattered into a different direction. Either way, they would no longer reach the observer on the ground. As a result, the observer detects fewer light rays from the star than he would have seen on an air-free planet. We call this dimming of stellar light extinction. The extinction depends on the distance in atmosphere light travelled [16]. It is described by airmass.

Figure 39: Airmass and zenith angle

Target is some angular distance away from the zenith, indicated by the zenith angle  $z$  in the diagram above, then its light travels a longer distance through the Earth's atmosphere before it can reach you [16]. Airmass is defined by below equation,

$$\text{airmass } X = \sec(z) \quad (10)$$

This extinction would decrease the apparent magnitude of star or satellite we observe [16]. It is very essential to consider the extinction factor. The linear

relation (Bouguer's law) between magnitude and atmospheric extinction is given by [16],

$$m(X) = m_0 + k \cdot X \quad (11)$$

Here  $k$  is atmospheric extinction coefficient.  $m_0$  is the apparent magnitude of object without earth's atmosphere. In the astronomy, different band filters are used for observation of objects. The reason behind filters is to analyze its components of object for certain H- alpha line etc. These different band filters have certain wavelength range. There are so many filters like U, V, R, G, I, B etc. V is visual band filter with wavelength range of 500 to 700 nm. R, G, and B stand for red, green, and blue, respectively. On average, V band has extinction constant value around 0.2 mag/airmass. U has 0.6 higher than any others because of ozone layer. So different band filters are used for various observations with less extinction [43]. Mostly, photometry system is used for measurement of atmospheric extinction. It is very dynamic with spatially and temporarily. Second order extinction is also introduced because of ozone and aerosol scattering.

In the atmosphere, Rayleigh scattering is occurred in large amount than ozone and aerosol scattering. Total extinction is given by below formula,

$$k_T = k_r + k_o + k_a \quad (12)$$

In the equation 12,  $k_r, k_o, k_a$  are due to rayleigh, ozone, and aerosol, respectively. Here  $k_o$  is independent on altitude of observer, because observer's range is in 0 - 1 km. Thus, no matter where we are, the ozone layer would extinct the light from the object at around 15 km. The value of total extinction is found by theoretical formulas or observation [?]-[17]. In the observation, reference star or standard star is taken. At different airmass, apparent magnitude is measured and profile between magnitude and airmass has been done. The slope of that curve gives the value of extinction at that position and time [16]. If it is linear in behaviour, then it is expressed as,

$$k_T = \frac{m1 - m0}{X1 - X0} \quad (13)$$

Equation 13 represents the slope of the curve where measurements are taken at  $X1, X0$  airmass position with value of  $m1, m0$  [16].

There are numerous equation for atmospheric extinction. In the 1999, V. mohan [44] had given set of equations for Rayleigh, ozone, and aerosol scattering. The set of equations are given below,

$$k_r(\lambda, h) = \frac{0.0095 \cdot e^{-\frac{h}{8}} \cdot \left[ 0.23465 + \frac{107.6}{146 - \lambda^{-2}} + \frac{0.93161}{41 - \lambda^{-2}} \right]}{\lambda^4} \quad (14)$$

$$k_a(\lambda, h) = 0.087 \cdot \frac{e^{-\frac{h}{1.5}}}{\lambda^{0.8}} \quad (15)$$

$$k_o(\lambda) = 839.4375 \cdot e^{-131(\lambda - 0.26)} + 0.0381562 \cdot e^{-188(\lambda - 0.59)^2} \quad (16)$$

Here  $h$  is altitude of observer in km.  $\lambda$  is in  $\mu m$ . Assumptions are taken here to simplify these equations like pressure and molecular density of air. The contribution of ozone scattering is large in wavelength around 590 nm.

The general formula for Rayleigh depends on molecular density, altitude, wavelength, and pressure. Aerosol extinction depends on the aerosol optical depth and altitude. Ozone extinction only depends on the concentration of it in dobson unit. The general forms are given by,

$$k_r(\lambda, P, h) = \frac{2.5A \cdot \lambda^{-(B+C\lambda+\frac{D}{\lambda})} P}{\ln(10)g(h)M} \quad (17)$$

$g(h)$  is equivalent to acceleration of gravity,  $P$  is pressure, and  $M$  is molecular mass of dry air.

$$k_a(\lambda) = \tau \cdot \lambda^a \quad (18)$$

$a$  is exponent of  $\lambda$ ,  $\tau$  is aerosol optical depth which depends on the altitude of the site.

$$k_o(\lambda) = I_o \cdot P_o(\lambda) \quad (19)$$

$P_o(\lambda)$  is ozone extinction template from MODTRAN library.  $I_o$  is the scale factor expressed in Dobson units. These parameters vary with location of observer and atmosphere's characteristics [44]. Whenever the light comes from the star or any object, atmospheric extinction decreases the magnitude and it plays very vital role for calculations of photons. The reduction of the apparent magnitude is calculated using considering below parameters, the height  $h$  is assumed to be 0.018 km. The height represents the height of the sensor from the ocean level. Another variable is the  $\lambda$  which is the incident color property of source or satellite in the equations 6 to 8. The extinction is varied accordingly the wavelength. The variation is given below,

Figure 40: Atmospheric extinction variation with wavelength at  $h = 0.018$  km

In the figure, it is apparent that the apparent magnitude of the satellite is decreased with increment of the wavelength. That means, the scattering or absorption occurs mainly at higher wavelength range. There is a bulge type shape in range of 530 to 650 nm wavelength. That is because of the ozone layer absorbs or scatters the UV range wavelength. 530 to 650 nm don't lie in the UV range, therefore, the scattering or absorption would be less. And the apparent magnitude is higher than other wavelengths. This variation is only for height at 0.018 km. Also, the maximum extinction is around 0.32 and least one is 0.16. That is very large number in terms of photon numbers.

That is the reason behind the location of the observatories in the mountains or high altitude. Because at high altitude, the extinction would be less because light don't need to pass through the troposphere. Below figure is describing the extinction at altitude of 8 km.

Figure 41: Atmospheric extinction variation with wavelength at  $h = 8$  km

From the image, it is visible that the maximum magnitude is around 0.07 and minimum is 0.02. That is negligible compared to ground level extinction.

## 8 Point source function

The image of the satellite from the earth look like a point. Within certain field of view in the sky, the satellite only illuminates certain pixels on the CCD. The point images are projected onto CCD in a different way. It follows certain distributions like Gaussian around the point in two dimensions. The point images are described by point spread function [45]. Before the point spread function, why the point image looks like a Gaussian distributed around a point?

The reason behind the spread of the point source object is due to the diffraction of the telescope's aperture. There is another diffraction effect from the atmospheric turbulence [7]-[10]. There is a particular limit after that the diffraction is dominated by atmospheric turbulence. Turbulence of the atmosphere is generated by temperature gradient or pressure difference between two points. The effects of turbulence are in various ways. For example, star which behaves as a point twinkle in the sky. That is because of the turbulence. This particular effects of turbulence on the point source is called as atmospheric seeing effect [7].

The atmospheric seeing effect shows the speckle like structure of the point source with Gaussian distribution [9]. The more the turbulence, the more number of speckles inside the image. That will make the image blurry.

#### (1) Diffraction limited to telescope aperture

The diffraction of the point source due to telescope aperture is given by,  $\frac{1.22 \cdot \lambda}{D}$ . Where  $D$  is the diameter of the aperture in meter.  $\lambda$  is incident wavelength of the light in meter [8].

Figure 42: Distribution of the intensity due to diffraction limited by telescope

From the figure 42, it is apparent that diffraction plays a role for this distribution. This distribution almost follows the Gaussian distribution with different standard deviation and mean value. Most of the distribution (80 %) are fall in radius of  $\frac{1.22 \cdot \lambda}{D}$ . In this model, the intensity outside this radius is ignored [7]-[8]. The magnitude of the Gaussian distribution is obtained by star's influx of the photons on the telescope. The standard deviation is defined by the fwhm (full width half maximum). fwhm is a width where intensity becomes half of its peak or maximum value. Generally, the fwhm of this diffraction effect is given by,  $\frac{1.028 \cdot \lambda}{D}$ . This fwhm varies with wavelength and diameter. From fwhm, the standard deviation of Gaussian profile is found by  $\sigma = \frac{fwhm}{2.355}$  [?]. And the maximum radius of the point source image on CCD would be equivalent to  $\frac{1.22 \cdot \lambda}{D}$  [47]. After deciding the magnitude, standard deviation, and maximum radius of the point source, it is put into the standard Gaussian equation. Here mean value is zero because the center is assumed as origin point. The Gaussian

equation is given by,

$$y = N \cdot e^{-\frac{x^2}{2 \cdot \sigma^2}} \quad (20)$$

Here,  $N$  is the magnitude of the intensity in ADU unit. To describe or project the distribution in 1024 X 1024 pixels CCD, the  $\sigma$ , and fwhm should be calculated in terms of pixels.

Suppose, the satellite covers circular size with diameter in 10 pixels. That means, the radius of the point will be 5 pixels. In the diffraction  $\frac{\lambda}{D}$  is a unit which remains constant for constant diameter and wavelength. If the wavelength is changed, the diffraction will be changes accordingly but the ratio between radius of the point source and fwhm will be remained same. Thus, using that concept, the satellite which covers 5 pixel circular point source will have fwhm around  $1.028 \cdot \frac{5}{1.22}$ . Here 1.22 is equivalent to point with radius of 5 pixels and 1.028 is fwhm of the diffraction limited by aperture. And that is equal to 4.21 pixel means the width of the Gaussian distribution where the intensity becomes half of its maximum value. Therefore, 4 pixel is the fwhm. The standard deviation of the distribution will be 1.78 or 2 pixel. The below figure shows the image of the point source satellite with covering 5 pixel radius circular disk in Gaussian distribution. Each pixel is illuminated by given gray scale which follow the Gaussian profile.

Figure 43: Distribution of the intensity due to diffraction limited by telescope on CCD

Figure 44: Gaussian distribution of the intensity due to diffraction limited by telescope

In the above figure, the diameter of the distribution is almost 10 pixels. Also, the maximum value of ADU is 50000 in gray scale. This effect of diffraction is related to telescope aperture.

## (2) Atmosphere seeing effect and diffraction

As mentioned before, the atmospheric seeing effect is due to the turbulence. If the intensity of turbulence is not very strong then diffraction is limited by telescope aperture but if the intensity is strong then diffraction is limited by atmosphere seeing effect [7]. As the light wave propagates through the atmosphere it experiences fluctuations in amplitude and phase. An image formed by focusing this wave exhibits fluctuations in intensity, sharpness and position which are commonly referred to as scintillation, image's blurring and image's motion. The diffraction angle is given as,  $\theta = \frac{3.812 \cdot 10^5 \cdot \lambda}{r_0}$ . The angle is given in arc second and  $r_0$  is fried parameter which is the variable with turbulence intensity. The fwhm is given as  $\text{fwhm} = \frac{2.013 \cdot 10^5 \cdot \lambda}{r_0}$  [7]-[10].

Figure 45: Gaussian distribution of the intensity due to diffraction limited by atmospheric seeing effect

Figure 46: Gaussian distribution of the intensity due to diffraction limited by atmospheric seeing effect

As mentioned earlier about the equivalent size of point in terms of pixels in diffraction due to telescope aperture, the same concept is applied here. Suppose the circular point has 5 pixels size. Therefore using  $fwhm = 2.013 \cdot \frac{s}{1.906}$ , the fwhm in terms of pixels would around 5.2 pixels or 5 pixels. Here 1.906 and 2.013 are the radius and fwhm of point in unit of  $\frac{\lambda}{D}$ . The  $\sigma$  standard deviation would be  $\sigma = \frac{fwhm}{2.355}$  and that would be 2.23 pixels. From the diffraction due to telescope aperture, the fwhm was 4 pixels and due to turbulence, the fwhm is 5 pixels. The profile of Gaussian distribution is described in the figures 45 and 46. It is apparent that turbulence effect or diffraction due to turbulence make the point source very blurry compared to aperture diffraction.

Figure 47: The blurring and scintillation of the star due to atmospheric seeing effect

In the figure 47, the turbulence changes the wavefront of the incoming light and deviates the position of the star. Also, it makes the image blurry. But, turbulence is very dynamic process, therefore, the movements of this star would be continuous. The blurriness and speckle formation of the point object will look like the below figure [9] and [10],

Figure 48: The blurring and scintillation of the star due to atmospheric seeing effect

But these effects of speckle and motion are ignored in the model to avoid more complexity. So this effect is dominant when the turbulence is very strong. At last, the fried parameter is given by,

$$r_0 = [0.184\lambda^{\frac{6}{5}} \cdot (\cos\gamma)^{\frac{3}{5}} \cdot \int dh \cdot C_n^2(h)]^{-\frac{3}{5}} \quad (21)$$

The unit of the  $r_0$  is in meters.  $\lambda$  is the wavelength in meters.  $\gamma$  is the zenith angle which is  $90 - \text{altitude of the satellite}$ .  $h$  is the altitude of the object in meters.  $C_n^2(h)$  is the refractive index structure coefficient at a specific altitude.

$C_n^2(h)$  is given as,  $C_n^2(h) = C_T^2 \cdot [7.9 \cdot 10^{-5} \cdot \frac{P}{T^2}]^2$  [7]-[10].  $P$  is the atmospheric pressure in milibars and  $T$  is the temperature in K. Now  $C_T^2$  is the temperature structure coefficient. And it is defined by,  $C_T^2 = \frac{[T(x) - T(x+r)]^2}{r^{2/3}}$ . Where  $x$  is a point within turbulence and  $r$  is another 3D distance from  $x$ .  $T(x)$  is the temperature at given point [7]-[10]. It is evident that higher energy turbulence breaks isothermal cells into smaller units, reducing the average distance between points of the same temperature: as turbulence becomes more extreme, the average  $C_T^2$  becomes smaller [9]-[10]. The fried parameter contains turbulence intensity, refractive index, pressure, wavelength. After all these parameters, the value of the fried parameter is calculated.

Based on the fried parameter, as mentioned, it could define dominant diffraction effect. The conditions are given below,

$$(1) \frac{D}{r_0} > 1$$

If the condition (1) is satisfied, the diffraction is limited to atmosphere seeing effect [7]. In diffraction, the wavefront of the point source should be equal to the size of the object which produces the diffraction. In condition (1) the  $D$  the diameter of aperture is larger than fried parameter. Therefore, turbulence will affect the point source diffraction. The fried parameter is equivalent to the object which produces the diffraction. Similarly second condition is,

$$(2) \frac{D}{r_0} < 1$$

Here the diameter is less than the fried parameter. Thus telescope aperture affects the diffraction of the point source object [47] and [8]. In the model, the  $T(x+r) - T(x)$  is taken as 0.01 K with  $r$  is 1 m. The pressure  $P$  is taken as 300 milibars which is equivalent to 1 atm. The altitude is taken as 500000 meters, the average distance between LEO satellite and observer.  $\lambda$  is taken as 500 nm in visible range. The average temperature is taken as  $T = 250$  K. After considering all these values in the equation 21. The fried parameter  $r_0$  comes out as 0.1189 m which is equal to 11.89 cm. That means turbulence brings the condition number (1) and diffraction will be dominated by atmosphere seeing effect. So this was the effect of diffraction on point source image in CCD image processing.

The size of the point image depends on the distance and real size of the satellite in the space. To find the radius of a point on CCD in terms of pixel, the resolution of CCD is used to discern the smallest distance on it [48]. Suppose CCD has 1024 x 1024 pixels and field of view of the site is around 0.05 x 0.05 degrees. Therefore, the resolution a pixel would be  $\frac{0.05}{1024}$ . The unit of this resolution is degree per pixel. That means each pixel covers around  $5 \cdot 10^{-5}$  degree. Based on that, radius of a point image is determined using this resolution. Now the real size of the satellite is come into picture to calculate the point size on CCD in terms of pixels. Suppose the radius of the satellite is around 25 m. Also, the distance between observer and satellite should be taken

to calculate the angular size of 25 m size satellite. Here, the satellite is taken as sphere or circular in shape. And the distance between observer and satellite is around 480 km (ISS zarya). To calculate the angular size of the satellite radius in degree, the ratio between radius and distance is taken [48]. Therefore, the calculation will be  $57.2958 \cdot \frac{25}{480000}$  and that is around 0.0029841 degree. Now using angular resolution of CCD which is mentioned before around  $5 \cdot 10^{-5}$ , the radius of satellite in pixels is calculated. The angular size of satellite and resolution is divided and the answer is  $\frac{0.0029841}{5 \cdot 10^{-5}}$  and that is around 60 pixels. That means 60 pixels are equivalent to the radius of  $\frac{1.22 \cdot \lambda}{D}$  or 1.22 unit. The general formula is given by,  $\frac{\theta \cdot P}{D}$ .  $\theta$  is angular size of the satellite in degrees and  $D$  is radius of the satellite in meters. Also,  $P$  is total number of pixels. Sometimes the CCD is not in perfect square shape. It could be rectangle shape with different pixels in vertically and horizontally. Suppose the CCD has 1024 x 620 pixels. Based on that, field of view will be changed but that will not differ the point size on CCD.

## 9 Image processing

The image processing is the conversion of analog form voltage or number of electrons to digital form [49]-[51]. The output of CCD is in voltage based on number of electrons. Higher the electrons in each pixel, higher the voltage. But CCD has a limit for each pixel around 10000 to 500000 electrons. Beyond that point, CCD will transfer electrons to next pixel and create effect called as blooming [5] and [52]. This blooming effect is undesirable and it could be avoided by set the proper gain or exposure time.

Figure 49: The blooming effect in CCD

In the figure, the pixels are saturated with total capacity. Beyond that capacity, it will pass the extra electrons to next place and this chain process will continue until it get saturated properly. But in this model, the exposure time

and full well capacity is most useful parameter to avoid this kind of phenomena.

CCD chip has size around 20 to 50 mm in width and length. The pixel has square shape with size of 20 to 40 microns. The resolution depends on the pixel's size. The small size pixels capture the influx of photons from the distant object. The very far star will have less flux of the photons, but increasing the exposure time could make the image more bright. But in our model, the output is magnitude of satellite. The magnitude is convertible into flux and from flux, we can find the number of photons which are imparted on CCD chip's single pixel.

The flux is found by below formula,

$$\frac{F_1}{F_2} = 10^{\frac{m_2 - m_1}{2.5}} \quad (22)$$

$F_1, F_2$  are fluxes for star 1 and 2. We know flux of sun  $1376 \frac{W}{m^2 s}$  on average [13]. Therefore,  $F_1 = 1376$  and  $m_1 = -26.58$  magnitude. But here in the model, the output of the magnitude is in visible range. It is not possible to consider the whole range of wavelength. Therefore, the flux density is very important. In astronomy, Jansky unit is useful to define the spectral flux density [13] and [53].

Also, the apparent magnitude of Vega star is around 0.0 and it is very realistic to use this value. Because sun's magnitude and flux vary with earth's orbital and axial rotation. But the flux of the Vega remains constant because of its large distance. Thus, in the equation 22, the  $m_1$  becomes 0.0 [54]. To calculate the average flux density in visible range for the Vega star, it is very useful to consider the bandwidth of the visible range. The bandwidth of the visible spectrum is around  $880A^0$ . And the central wavelength of the spectrum is  $5440A^0$ . Based on these values, the flux from the Vega star in visible range is found. The  $F_1$  flux density is  $363.1 \cdot 10^{-11} \frac{erg}{cm^2 s A^0}$  [55]. After multiplying this value with central wavelength and bandwidth, it will give the total flux in visible range for Vega star. From the above equations, we can derive magnitude of satellite  $m_2$ . This will give the  $F_2$  flux of that object. Reference star like sun or vega has to be taken to calculate the flux of the satellite. After putting all values in equation 22,

$$F_2 = 363.1 \cdot 10^{-11} \cdot 10^{-\frac{m_2 + 0.0}{2.5}} \quad (23)$$

From flux, photon number is easily obtained using  $E = h\nu$  where  $\nu = \frac{hc}{\lambda}$ , area of telescope and exposure time. The unit of flux is per unit area unit time and unit wavelength. But the flux is given in erg and that is converted into joule. Multiplication with central wavelength will make the unit of flux per unit time and area. The central wavelength is taken in mid visible range. Time is the integration time or exposure time of system. And last one is area of telescope aperture. The incoming photons which are coming from the star or satellite always come through the telescope aperture. After the optics manipulation, the

flux is concentrated on some parts of pixels on CCD. The multiplication of these parameters will give the final total number of photons.

Wavelength is the incident photon color's property. Here, magnitude is in visual band, therefore, the bandwidth of the visible range is multiplied. The final equation is given by,

$$n = \frac{F_1 \cdot \lambda_{central} \cdot \lambda_{bandwidth} \cdot 10^{-\frac{m_2+0}{2.5}} \cdot TA}{hc} \quad (24)$$

From the equation,  $\lambda_{central}$  is the central wavelength of the visible band around 5440 Angstrom.  $\lambda_{bandwidth}$  is the bandwidth of the visible range around 880 Angstrom. After putting the values inside the equation 24,

$$n = \frac{363.1 \cdot 10^{-11} \cdot 5440 \cdot 880 \cdot 10^{-10} \cdot 10^{-\frac{m_2+0}{2.5}} \cdot TA \cdot 10^{-7}}{hc} \quad (25)$$

In the equation,  $10^{-7}$  is the conversion factor from erg to joule unit. The factor  $10^{-10}$  is the conversion scale from Angstrom to meter. After putting exposure time around 1 s, area of the telescope aperture in  $cm^2$  as  $\pi \cdot 0.6 \cdot 0.6 \cdot 1000$ , for the satellite with apparent magnitude around -3.0, the total number of photons will be 15684711149.45316 and that is the very big number. Here the radius of the aperture is taken as 0.6 m. This large number is the total number of photons coming from the star or satellite with -3 apparent magnitude in visible range towards the 0.6 radii aperture within 1 s of exposure time. That's the shortest explanation of the total number photons to the CCD.

From the equations, it is apparent that exposure time is again playing very important role to change the flux accordingly. In astronomy, the exposure time varies from object to object. It could have ms or hours as a unit. But the CCD doesn't count the exact number of photons. On CCD, each pixel will be illuminated with photons and these photons are converted into electrons to measure the intensity of the star in form of the voltage. But during the conversion of photon to electron by silicon diode in pixel, some of the photons are converted into electrons. That means, if the pixel is getting around 1000 photons that doesn't mean the converted electrons will be the exact 1000. It could be 500 or 700 based on the efficiency of the CCD. That efficiency is called the quantum efficiency [56] and [5]. The quantum efficiency just give the wrong number of flux not the wavelength. Thus, quantum efficiency is multiplied with total number of photons to find the generated electrons in a pixel. The equation will become  $n_e = Q.E. \cdot n$ , where  $n$  is the incident photon number and Q.E. is the quantum efficiency. The final converted electrons will be  $n_e$ . This quantum efficiency is dependent on the wavelength which is incident on the CCD. Here it is given the variation of the quantum efficiency with wavelength [56],

From the table 6, it is apparent that in the visible range or visible wavelength line 550 nm, the quantum efficiency is around 60 %. That means in the incident of 100 photons with wavelength of 550 nm, the 60 electrons will be generated. The actual value of the pixel changes due to the quantum efficiency.

Table 6: Quantum efficiency variation with wavelength

Wavelength (nm)	Quantum efficiency
307	5.96
323	8.93
336	11.91
349	15.88
360	19.85
370	23.33
380	27.3
399	30.277
425	32.74
443	35.72
454	40.18
464	44.65
475	47.13
485	45.63
498	43.64
514	46.61
524	49.59
537	53.56
553	59.02
566	62.49
574	66.47
582	66.96
589	66.96
608	62.96
634	64.43
665	63.42
683	58.93
697	53.94
717	50.94
741	50.43
757	45.94
767	41.95
783	37.46
796	32.98
817	32.46
843	31.45
874	27.94
895	25.44
913	20.95
924	17.46
937	14.47
950	9.98
971	6.48
997	7.46

After considering, the white noise, read out noise, flicker noise, dark noise, shot noise, sky background and its related noise, quantum efficiency, exposure time, bandwidth, visible wavelength, the final number of photons are obtained using the final equation 25 with multiplication of quantum efficiency. In the CCD, the electrons or voltage is a analog form which is needed to be converted into the digital form. In the conversion process, the transformation from analog to digital occurs with particular frequency. If the frequency of this conversion is not at certain limit, it will make the image blurry and very unclear. This effect is called Aliasing effect [12]. Aliasing is the process or effect that occurs in every signal processing like here in the CCD.

The voltage form of the CCD is the sample and this sample should be uniquely converted into digital or indistinguishable parts such that it looks like continuous form like original sample in analog form. Aliasing effect has two types: the temporal and spatial effect. In this model, the spatial aliasing effect will occur.

Figure 50: The Aliasing effect during the sampling process

In the above figure, it is spatial aliasing effect where the original analog form is not properly sampled during the processing inside the camera. The edges of the cherry is very clear from the looking at it. To reduce it, there are filters for anti-aliasing effect to reduce it.

The aliasing effect occurs when the sampling rate is below certain limit. This is called Nyquist theorem [11]. It is very useful for digitization of the continuous form image. This frequency which is frequently mentioned here called as sampling rate or number of samples per second. The theorem says, the sampling rate should be equal or higher than the  $d/2$ . Where  $d$  is the smallest object. The Nyquist Theorem states that in order to adequately reproduce a

signal it should be periodically sampled at a rate that is 2X the highest frequency you wish to record [11]. With images, frequency is related to structure size. Small structures are said to have a high frequency. If the frequency is less than this limit, the aliasing effect will dominate the image.

Figure 51: The sampling frequency greater than the limit or oversampling

This is oversampling and it will not make the image bad but the data samples will become such large that it would take several time to get output.

Figure 52: The sampling frequency equal to the limit

Figure 53: The sampling frequency less than to the limit or under-sampled

In the under-sampled rate, the aliasing phenomena shows its nature into the image [57]. In the model, the aliasing effect is removed by considering the image or satellite as point source function with Gaussian distribution.

Now the last step is remain to convert the number of electrons into the ADU or digital unit form using the pixel's well capacity. Normally, the pixel's well capacity is around 100000 to 1000000 electrons. Beyond this capacity it will

show the blooming effect which is mentioned above in the figure 49. And that problem is solved by adjusting the exposure time or gain capacity of the well. In astronomy, the output of the image is in the gray scale. In short, it looks like black and white image. The astronomer converts this gray scale image into the color image by passing or converting them using color band-pass. They green, red, and blue pass filters to create the color image. The gray scale image comes in 16 bit int or float type or 8 bit int or float. The higher the bit size, the higher the resolution of the image. Thus, the 16 bit image has high resolution than 8 bit image. In the 16 bit or 8 bit image, the possible gray value of each pixel will be  $2^{16} - 1$  or  $2^8 - 1$  which are equivalent to 65536 or 255 [?]-[51]. Therefore, the 65536 is the maximum gray value in the 16 bit CCD and it will denote the color almost white. The collected electrons is converted into the gray value by simple ratio,  $65536 \cdot \frac{n_e}{100000}$ . Here 100000 is the maximum well capacity which could be held by a pixel. 65536 is the maximum gray value of the 16 bit CCD, and  $n_e$  is the collected electrons from the point or extended source from the sky. Suppose, the  $n_e = 10000$  then the gray value for that pixel would be 6553 not 6553.6 because it is 16 bit int not 16 bit float. Therefore, associated gray value will be given to that pixel [?]. After considering, apparent magnitude, atmospheric extinction, aliasing effect, point source function, different noise and quantum efficiency, the satellite trails is formed using Python. The results of the satellite trails for different satellites are given in next subsection.

## 9.1 Result of satellite trails

**(1) ISS (Zarya) Satellite trails :** The trails of the satellite is obtained by considering aforementioned essential factors. The specification of the image of trails is given as follows: The field of view is taken as 56.68 X 56.72 in degrees for altitude and 285.72 X 285.77 degrees in azimuth. That means the sky is covered in range of 0.05 X 0.05 degrees assuming that CCD chip is a square. Also, the diameter of the telescope aperture, pixel's size, and number of pixels are taken as 1.2 m, 13 microns, and 1024 X 1024. The satellite trails is simulated during 2020/6/5 at 6:53:34. The average distance between observer and satellite is around 508 km and time of flight of the satellite within field of view is around 0.04 seconds. The CCD is assumed to be 16 bit with well capacity of 100000 electrons.

Figure 54: The image of trails during the flight of the satellite ISS

From the figure 54, it looks like the satellite is not clearly visible even if the distance is around 507 km. The reason is the phase angle of the satellite with sun and observer. The less phase angle couldn't illuminate the satellite properly. But the maximum digital form or ADU of each pixel is around 26000. Also, the satellite passed through this view within 0.04 seconds.

Figure 55: Noise distribution

In the figure 55, the y-axis describes the ADU value of the frame. The noise is very random due to the distributions. This profile includes all above-mentioned noises.

Figure 56: Satellite trails of ISS

The above figure shows the another trails of the same satellite. This time the illumination is higher than first image. The satellite trails model is designed in such way that the satellite would pass through the center of the field of view. Now the satellite trails of the debris would be invisible with naked eye because of the high apparent magnitude. The average size of debris of Microsat - R is around 10 to 50 cm [42]. And the albedo of these debris are around the 0.2 to 0.5 depends on the surface. The satellites trails of the debris is obtained on 2020-4-28 at 12:29:30 UTC. The field of view is the same 0.05 degrees. The altitude and azimuth are in range of 42.7 to 42.75 degree and 157.21 to 157.26 degree, respectively. The average distance between observer at 49.0143, 72.7751 and debris is 418 km. And the passing time of the debris within field of view is around 0.06 sec.

Figure 57: Satellite trails of Microsat - R

The satellite trails of the debris is at maximum of around 10000 ADU. Also, the geosynchronous satellite is very hard to see with naked eye. Therefore, the results of the trails are promising to describe its motion and TLE which is described in the next section.

## 10 Future scope in TLE from optical observation of the satellite

TLE of any satellite body comes from the optical observations of the trails in the sky. Using various algorithms and observations, TLE of the satellite orbit is determined. The most major orbital elements are inclination, ascending nodes, eccentricity, mean anomaly, semi major axis, mean motion and argument of perigee. To get these elements, fundamental variables like velocity, position, distance from earth's center are necessary to know for the algorithm. The multiple observation could determine the drag and other perturbations of the trajectory. Many software and algorithms are made to get TLE of the satellite [58], [59], [60]. People have worked upon this field but the perturbations and B star coefficient are hard to get. So this work would be appreciable in the future study.

## 11 Discussion and Conclusion

Using SGP4 model, the satellite's position is easily found using mathematical equations and some perturbations. The accurate results of the model describe the inclusiveness and flexibility. The results in Alt-Az and Ra-Dec for ISS (Zarya), Microsat - R, and QZS - 1 satellite are found with help of the model. The generated results are further used in simulation of the satellite trails. The simulation of trails is obtained through considering the CCD's noises, atmospheric extinction, diffraction due to turbulence and telescope aperture, apparent magnitude, quantum efficiency and albedo of the satellite.

The noises of CCD contain read out, dark, shot, sky background noise. Also, the satellite is assumed to be circular point source in the sky. And the point source function which follows the Gaussian profile has been taken for the imaging. The point source is diffracted by turbulence and telescope aperture and its effect on fwhm is also taken. Then the illumination pixels on CCD is considered and its relation with incident photons. The ADU unit and gray value is associated with incident photons or apparent magnitude of the source. Also, the apparent magnitude is attenuated by atmosphere due to scattering and absorption of the light. The atmospheric extinction, noise, diffraction, and digital form of the CCD's pixels voltage form generate the satellite trails within certain field of view which depends on the magnification of the telescope.

After the satellite trails, the inclination, eccentricity, ascending nodes, mean motion and other satellite orbital elements could be found using observational study of the satellite. These observations provide the information about the TLE of the satellite. The future work on the generation of TLE from the observational data of satellite trails is excellent. Also, the problem of collision between satellites and generation of debris could be solved if the futuristic trajectory of the satellite is known. Also, there are other models for geosynchronous satellites and incoming satellite in the earth's atmosphere. Using these models, the future of the object is determined and these are the future work in this field.
